Working Paper No. 2011/60

Halving Poverty in South Africa: Growth and Distributional Aspects

Distributional implications of halving poverty in South Africa

Fiona Tregenna*

September 2011

Abstract

The United Nations Millennium Declaration commits to halving extreme poverty between 2000 and 2015. The South African government has set a goal of halving poverty by 2014, although the meaning of this goal has not yet been defined. This article specifies government's stated target of halving poverty by 2014 in terms of specific measures of the poverty gap and poverty headcount ratio, using income and expenditure survey microdata. With the poverty line as defined here, approximately half the South African population falls below the poverty line. Despite this, the aggregate poverty gap is surprisingly small at about 3 per cent of GDP. Projections of the effects of distributional scenarios on poverty indicate that halving poverty appears feasible with moderate growth rates and fairly mild pro-poor distributional change.

1   Introduction

Sixteen years after the ending of Apartheid, poverty remains very high in South Africa. Over 10 per cent of people in South Africa live on less than US$1 a day, whereas in countries with similar levels of income per capita (such as Chile, Turkey, Malaysia, or Costa Rica) typically less than 2 per cent of their population fall below the US$1 a day line, and even comparable countries such as Brazil have less than 10 per cent of people below this line. Over a third of South Africans live on less than US$2 a day, whereas in comparable countries typically between 10 and 20 per cent of the population falls below this line.[1] Unsurprisingly, inequality in South Africa is extremely high by international standards, with a Gini coefficient of 0.67.[2]

The United Nations Millennium Declaration includes a commitment to halve extreme poverty between 2000 and 2015, measured in terms of the proportion of people living below US$1 per day. The South African government has targeted the halving of poverty by 2014, although exactly what this means in economic terms is yet to be elaborated and a national poverty line is still being developed, in terms of which government's target is to be framed.

This study takes as a starting point the target of halving poverty by 2014, as set out in the 'Accelerated and Shared Growth Initiative – South Africa' (AsgiSA) strategy announced by the South African government in 2006. The most recently available income and expenditure data are used to measure current levels of poverty, and thus to quantify what the halving of poverty would actually mean. This allows for an evaluation of the feasibility of halving poverty by 2014. The intention in this article is thus not to comment on the intrinsic merit of halving poverty as a public policy objective. Rather, it is to concretise this objective in economic terms, to assess its feasibility, and to analyse under what growth and distributional scenarios the target could be achieved. Growth can potentially play an important role in reducing poverty; this study evaluates how far growth might reasonably go towards halving poverty. The analysis does not, however, deal with the potential effects of distributional change on growth.

The issues being analysed here have important policy implications. The South African government is currently in the process of unpacking what the target of halving poverty means, and this research is thus directly relevant to policy makers as well as to economists concerned with issues of distribution and poverty. The projections presented here of poverty under various growth/distributional scenarios have clear analytical and policy implications. Furthermore, since no research has yet been published measuring poverty using the most recently available data, this contribution is important in bringing to light the current state of poverty in South Africa.

The existing literature generally points to an increase in poverty in South Africa in the late 1990s (see for instance Hoogeveen and Özler (2005); Leibbrandt et al (2004); Simkins (2004); Pauw and Mncube (2007); Meth and Dias (2004) and Ardington et al. (2005). A study published by the South African government (Government of the Republic of South Africa 2008) claims declines in both the poverty gap and the poverty headcount ratio between

---

[2] In terms of household per capita expenditure. For an empirical survey of inequality in South Africa, see Tregenna and Tsela (forthcoming 2012).

1995 and 2005, and attributes this decline primarily to government's social welfare grants. Some studies, such as Van der Berg et al (2005), point to a decline in poverty between 2000 and 2004. The generally unimpressive record of income poverty reduction since the advent of democracy in South Africa highlights the challenge of significantly cutting poverty. Countries such as Chile and to a lesser extent Brazil have made significant progress in reducing poverty in recent years, through dedicated programmes centred around targeting spending on the poor. Halving poverty by 2014 in South Africa, as per government's commitment, would arguably require a significant shift given the apparent stubbornness of poverty levels thus far.

Section 2 below quantifies what the 'halving of poverty' could mean, by setting out a monetary poverty line, clarifying two relevant measures of poverty, and by using the latest income and expenditure survey data to put figures to the target of halving poverty. Section 3 projects the poverty headcount ratio and poverty gap in 2014 under various growth scenarios, considering specifically whether poverty can be halved through growth under the current distributions of income and expenditure. Section 4 analyses the effects of various combinations of growth and distributional change on poverty, and Section 5 discusses the broader implications of the findings. Section 6 concludes.

2   The target of halving poverty

a)   Data

The various datasets of the 2005/2006 Income and Expenditure Survey (IES) were utilised for this analysis. These are the official national household surveys produced by the national statistical agency, Statistics South Africa.[3] All data were inflated or deflated to March 2006 (depending on when the household was surveyed), using monthly CPI data. Both income and expenditure/consumption are shown in initial analysis, but the subsequently focus is on expenditure/consumption since this is most relevant to poverty. All calculations were undertaken on a household per capita basis, as elaborated further below.

---

[3] The original datasets were accessed through the South African Data Archive of the National Research Foundation. In line with Statistics SA definitions and international best guidelines (see for instance United Nations University World Institute for Development Economics Research 2008), expenditure/consumption has been calculated to include the following categories: food and beverages; tobacco and narcotics; clothing and footwear; housing, water, electricity, gas and other fuels; furnishings, household equipment and routine maintenance of the house; health; transport; communication; recreation and culture; education; restaurants and hotels; miscellaneous goods and services (which includes personal care; personal effects; social protection services; insurance; other financial services); and other services not elsewhere classified. Income has been calculated to include the following broad categories: income from work; income from capital; pensions, social insurance, family allowances; income from other individuals; other income; and income from imputed rent on owned dwelling (calculated as 7per cent of the value of the dwelling per annum). Not included in either income or expenditure are the estimated values of in-kind income or expenditure respectively; savings, debts, taxes, transfers made to others; loss incurred in obtaining income; and other products not consumption (such as interest on mortgage bonds; non-refundable bursaries; and the imputed costs of home production).

b) The poverty line

AsgiSA does not define precisely what is meant by 'poverty' and hence what a 'halving of poverty' would actually mean. The Minister of Finance announced in his 2005 Budget Speech that a poverty line would be developed for South Africa. A process has since been underway, led by National Treasury and Statistics SA, to develop a national poverty line, and the official government targets for halving poverty are then to be framed in terms of that line. This study therefore uses the proposals contained in the official Statistics SA/National Treasury Discussion Document (2007) as a starting point to derive an appropriate line for this study.[4] This is a semi-normative poverty line based on a cost of basic needs approach. Statistics SA calculates a food poverty line at R211 [US$31][5] per capita per month (in 2000 prices).

This is intended to represent the minimum amount required to purchase enough food to meet an average person's basic daily food-energy requirements over a month. The measure is based on the daily energy requirement of 2,261 kilocalories per capita, as recommended by the South African Medical Research Council. Statistics SA then calculated the cost of meeting this minimum energy requirement, in the light of the types of foods commonly available to low-income South Africans. As discussed later, this measure does not take account of differences in nutritional requirements by age or gender. Statistics SA then estimates the non-food component of a poverty line as R111 [US$17] per capita per month. This is based on the assumption that the non-food items typically purchased by a household that spends about R211 per capita per month on food can be treated as essential, as such households are effectively forgoing food consumption to purchase these non-food items. The overall poverty line is approximately one-and-a-half times the food poverty line. In Latin American countries, the poverty line is typically set as double the food poverty line. This yields a total poverty line of R322 [US$48] per capita per month in 2000 prices.

The US$2 a day measure of poverty that is commonly used internationally translates to about R162 per capita per month in 2000 prices (Woolard and Leibbrandt 2006). This is about half of the minimum poverty line which Statistics SA calculates, and is significantly below even the essential food component of the poverty line calculated as being necessary to meet minimum daily energy requirements. The US$2 poverty line has been widely criticised (see for example Reddy and Pogge 2008).

Statistics SA bases the household poverty threshold on a pooling of resources within households, with equal weighting given to all members of the household (i.e. without using any adult equivalence conversions, economies of scale, or other scaling). In other words, the poverty threshold for a household of five people would simply be [5 x R322 = R1610 per month] (in 2000 prices). An alternative approach to calculating a per capita poverty line and comparing this line to income or expenditure calculated on a per capita basis would be to take account of differences in nutritional requirements for people of different ages and genders; such an approach is discussed at the end of this section.

---

[4] A full analysis of poverty would of course need to take into account the various monetary and non-monetary dimensions of poverty. These include not only the absolute level of income or expenditure, but also relative poverty, the meeting of basic needs, human dignity, and capabilities. The use of a monetary poverty line in the analysis that follows is not intended to undermine the importance of these aspects. However, the use of a specific line is necessary for empirical analysis of the relationship between growth, distribution, and poverty.

[5] The conversion of figures from South African Rands to US$ in this article use the exchange rate in 2006 of R6.76/US$ for consistency, since the analysis is based on 2006 data.

Drawing on the Statistics SA/National Treasury Discussion Document as well as discussions on the issue with Statistics SA officials involved in the process, this study uses as a basis the lower poverty line suggested in the Discussion Document (R322 per capita per month in 2000 prices). This R322 baseline needs to be inflated from 2000 prices to March 2006 levels for use with the 2005/6 IES data in the analysis that follows. Statistics SA inflates the 2000 figures using the CPI index for metropolitan areas only. This is flawed, particularly given the rural bias of poverty in South Africa. Further, given that CPI rates for the lower income quintiles tend to exceed those for the higher quintiles, the use of an overall CPI measure is inappropriate for inflating a measure which is relevant to people living in poverty, if the intention is to cost the same basic basket of goods deemed necessary in 2000. In order to construct an appropriate inflator index, this study thus uses the CPI rates for the lowest two quintiles for all areas (metropolitan, other urban, and rural) in order to inflate the 2000 poverty line to March 2006 prices. The mean of these CPI rates for the lowest and second-lowest quintiles are used, given that these are most relevant to the basket of goods consumed by the poor.

The use of this inflator indices results in the poverty line of R322 in 2000 prices being converted to a line of R450.48 [US$67] in March 2006 prices (as opposed to R422.46 when the overall CPI for urban areas is used). March 2006 is used because this is the month to which the 2005/06 figures are calibrated. The baseline poverty line used in the analysis which follows is thus R450 [US$67] per capita per month (or R5 400 [US$800] per capita per annum) in March 2006 prices.

Some parts of the analysis also consider the effects of using the 'food poverty line' as calculated by Statistics SA. This includes only the food items needed to meet minimum energy requirements, and excludes the costs of clothing, shelter, transport, and so on. This was calculated by Statistics SA at R211 per capita per month (in 2000 prices) which translates to R295 [US$44] per month in March 2006, for use with the 2005/6 IES data.

A limitation of a household per capita poverty line, such as the one proposed by the government and updated here, is that it does not take account of differences in the demographic composition of households (specifically in terms of age and gender) and the concomitant different nutritional requirements of different people. More specifically, young children have daily nutritional requirements below those of adults, and to a lesser extent females' requirements are below those of males; it follows that households with relatively high composition of young children and/or of females will have lower per capita energy requirements. To the extent that these differences are correlated with income differences—for example if poorer households have a higher composition of young children and women than the average—this could lead to an overestimation of poverty. An alternative approach would be to calculate a poverty line for a specific demographic, such as adult females, and to calibrate household members in terms of their nutritional requirements relative to that benchmark demographic. This means that, given two households with the same income/expenditure and the same number of members but different demographic compositions, one household could be classified as falling above the poverty line and the other below it.

Following this alternative approach, a 'female-adult-equivalent' poverty line was also derived, based on a study of average daily energy requirements by age and gender produced by the national Department of Health (Tshitaudzi 2007). That study estimates the minimum

daily nutritional requirement of an adult female as 2,145 kilocalories, which was costed (based on the same costing model utilised by Statistics South Africa), the non-food component added in, and inflated to March 2006 prices (in the same manner as described previously) yielding a female-adult-equivalent poverty line of R435 per month. The number of female adult equivalents in each household can be calculated, based on the age and gender of each member of the household and using the relative minimum nutritional requirements as per the Department of Health Study, and hence the income and expenditure per female adult equivalent of each household can be computed. This allows for a determination of whether members of a household collectively lie above or below the poverty line, and in the case of the latter the calculation of their poverty gap as well. Poverty rates using this alternative measure of a poverty line are discussed in section 2(d).

c) Measuring poverty

Setting the level of a monetary poverty line answers only part of how to gauge poverty, and hence how to define what halving poverty would mean. One way of measuring poverty is the poverty headcount ratio,[6] and this is the measure that government seems inclined to use to quantify poverty.

The poverty headcount ratio measures the incidence of poverty, which is an important dimension of poverty. The simplicity of this measure may make it intuitively appealing from a policy perspective. However, the poverty headcount ratio gives no indication of the intensity of poverty. The actual incomes of all the people falling below the poverty line do not enter into the poverty headcount ratio in any way.

The intensity of poverty can appropriately be measured not by the poverty headcount ratio but by the aggregate poverty gap, which sums the gaps between the poverty line and the income or expenditure of everyone falling below the poverty line.[7]

The choice of poverty measure has significant policy implications, particularly insofar as specific targets for the reduction of poverty are part of government policy. The purpose of a 'target' is not only to evaluate outcomes but to inform policy design and implementation. The poorest people are highly unlikely to be lifted above the poverty line in the near future, and any increase in their incomes will have no impact on the poverty headcount ratio. To the extent that success in poverty reduction is measured exclusively in terms of the poverty headcount ratio, this could de-emphasise raising the incomes of the poorest people. This is

---

[6] The poverty headcount ratio H is the proportion of the population falling below the poverty line, and can be formally expressed as $H = \frac{1}{n} \sum_{i=1}^{n} g(y_i \mid y_p)$ where there are n individuals with expenditures or incomes y_i arranged in ascending order such that $0 \leq y_1 \leq y_2 \leq ... \leq y_n$. The poverty line can be denoted by y_p and let $g(y_i \mid y_p) = 1 \mid y_i < y_p$; $g(y_i \mid y_p) = 0 \mid y_i \geq y_p$. The poverty headcount ratio is typically expressed as *100H*, showing the percentage of the population falling below the poverty line. The incidence of poverty can also be measured simply as a poverty headcount (i.e. the actual number of people falling below the poverty line, rather than as a proportion of the population). However this is less desirable than a ratio as it gives a less meaningful sense of the extent of poverty, and population changes can also obscure the interpretation of changes over time.

[7] Using the same notation as in the previous footnote, the poverty gap G can be formally expressed as $G = \sum_{i=1}^{n} g_i$ where $g_i = max(y_p - y_i, 0)$.

particularly important when, as will be seen below, about half of South Africans can be classified as poor. Measuring the halving of poverty solely in terms of the poverty headcount ratio could imply a focus on the second quartile of the population (i.e. the second quarter from the bottom of the population) and not the poorest quartile.

Given the important shortcomings of the poverty headcount ratio, and the information about the intensity of poverty conveyed by the aggregate poverty gap, it seems advisable that the AsgiSA target of halving poverty be framed not only in terms of halving the poverty headcount ratio but also in terms of halving the poverty gap. While this formulation may lose some of the appealing simplicity of using only the poverty headcount ratio, it seems justified by a more comprehensive standard of measure. The analysis that follows uses this dual measure of the 'halving of poverty', in terms of halving both the poverty headcount ratio and the aggregate poverty gap.

d) Framing the target of halving poverty

A monetary poverty line has been specified for the purposes of this analysis, and we have set out a rationale for the measurement of poverty in terms of both the poverty headcount ratio and the aggregate poverty gap. Finally, concretising the meaning of halving of poverty by 2014 requires the specification of a starting point. AsgiSA was however formally launched in February 2006. The 2005/06 IES data (indexed to March 2006) are used as the baseline starting point for analysing the halving of poverty.

Employing a baseline poverty line of R450 [US$67] per capita per month yields a poverty headcount ratio of 52.45 per cent (using expenditure) and 49.56 per cent (using income) in 2006. In other words, roughly half of South Africans fall below this poverty line. The aggregate poverty gap comes out at just under R60 billion – (R59.65 billion using income and R59.82 billion using expenditure, equivalent to US$8.8 billion).

With the food poverty line of R295 [US$44] per month, the poverty headcount ratio would be 34.36 per cent and the poverty gap R21 billion [US$3.1] using expenditure; 33.86 per cent and R22.3 billion [US$3.3 billion] using income. Double the food poverty line – which is a poverty measure commonly used in Latin American countries in particular – yields a poverty headcount ratio of 62.27 per cent and a poverty gap of R105.7 billion [US$15.8] using expenditure; or 57.94 per cent and R102.7 billion [US$15.3 billion] using income.

An alternative approach to deriving a poverty line was discussed in section 2(b), taking account of demographic differences between households to compute a line based on female-adult-equivalent nutritional requirements and households' female-adult-equivalent income or expenditure. Using this line, the poverty headcount ratio comes out at 51.87 per cent (using expenditure) and 48.87 per cent (using income). The poverty gap would be R56.21 billion for expenditure and R55.6 billion for income. These figures are very similar to those derived using the household per capita poverty line, particularly for the headcount ratio. This suggests that differences in the demographic composition of the halves of the population above and below the poverty line have only a minor effect on the calculation of the poverty gap using minimum nutritional requirements averaged across age and gender (as in the household per capita method used by Statistics South Africa).

The empirical analysis in this study is thus conducted using the household per capita poverty gap. This measure is appealing in that the number of people designated as falling below a poverty line counts actual people, as opposed to adult-female-equivalents. For instance, cutting the poverty headcount measure when using the adult-female-equivalent approach does not actually mean that half as many people fall under the poverty line as previously, but rather that half as many female-adult-equivalents fall under the poverty line as previously. In the case of the household per capita measure, the fact that it refers to actual people is especially valuable given that this analysis is policy-oriented. Furthermore, the primary focus here is on taking the poverty line which government seems to be planning on adopting, as well as government's target of halving poverty by 2014, fleshing these out and most importantly looking at under what combinations of growth and distributional scenarios poverty could be halved. If poverty rates were dramatically different when calculated on the basis of a female-adult equivalent measure, this could be a reason for presenting the empirical results using this measure despite it being less heuristically appealing. But given that it does not make much difference to the empirical analysis, all results shown below are on the basis of the household per capita measure.

Given that both the income and expenditure poverty headcount ratios are in the region of 50 per cent, the 'halving of poverty' target can be approximated as involving the following two components:

- cutting the poverty headcount ratio to 25 per cent of the population by 2014;
- reducing the aggregate poverty gap to R30 billion[8] [US$4.4 billion] by 2014.

It is worth noting that, although about half the population is classified as poor, the poverty gap is only about 3 per cent of GDP.

The analysis of the relationship between distribution, growth, and poverty that follows is based on how these targets can be achieved. The actual policies that could be implemented to address poverty or change distribution fall outside of the scope of this article. Rather, the focus is on what the commitment in AsgiSA to halving poverty means in terms of growth and distribution, and under what growth/distributional scenarios these targets can be achieved.

3   Can poverty be halved through growth?

In order to establish whether the AsgiSA target of halving poverty can be achieved through distributionally neutral growth, various growth rates are applied uniformly across each of the 47,391,192 individuals in the (weighted) dataset.

Since the poverty line is a monetary poverty line based on the cost of a basket of goods, it remains constant in real terms. This means that, with any positive growth, there will be reductions in the poverty gap and headcount ratio, so long as there is not a worsening of distribution affecting the bottom half of the population.

AsgiSA sets GDP growth targets of at least 4.5 per cent between 2005 and 2009, and at least 6 per cent between 2010 and 2014. We consider how poverty would evolve by 2014 with these rates and the current distributional structure. However, these rates are targets and not

---

[8] In March 2006 Rands.

projections or forecasts. Furthermore, realistically it seems inconceivable that these rates will actually materialise, particularly in the light of the global economic problems.

Two sets of growth forecasts are also used. Firstly, the growth forecasts put out by the National Treasury for the years 2010-2012 (National Treasury, 2010), combined with the actual growth rates for 2007-2009. Since official forecasts are not available for the years 2013 and 2014, the 2012 forecasts are extended for these two years. Secondly, we use the growth forecasts put out by the major private banks in South Africa for the years 2010 onwards, again combined with actual growth rates for 2007-2009 (see ABSA 2010; Bruggemans 2009; Nedbank 2010; and Standard Bank 2010). In summary, the AsgiSA growth targets translate to average annualised GDP growth of 5.43 per cent per annum over the period 2006-2014, while the forecasts of the National Treasury and the averaged forecasts of the private banks translate to 2.94 and 3.11 respectively.

For comparison purposes, GDP in South Africa grew at a real average annualised rate of 4.1 per cent between 2000 and 2006, which was higher than for many years previously, and 2.4 per cent between 2006 and 2009.[9] These rates were reached during the recent commodities boom from which South Africa benefited, and which is unlikely to continue in the near future. The recent downturn in the world economy, which is also affecting South Africa, will in all probability result in a decline in growth rates. It goes without saying that this would make it even more difficult to attain the poverty targets than is shown here.

These three different growth rates are applied uniformly across the distribution to ascertain the effects on poverty. Note that this only means that people gain uniformly in proportionate terms; in absolute terms the wealthy of course gain many times more than the poor with a uniform growth rate.

Tables 1 and 2 show what the halving of poverty would mean in terms of the poverty headcount ratio and aggregate poverty gap. Tables 3 and 4 thereafter show the same using the food poverty line. These results are shown in terms of each of expenditure and income, but in the subsequent analysis the focus is on expenditure since this is most directly relevant to measuring poverty. In each case the poverty gap and headcount ratio in 2014 are projected under three growth scenarios (using AsgiSA targets, Treasury forecasts, and the banks' forecasts), given the current distribution of income or expenditure. In other words, this shows how far growth alone would go towards meeting the targets of halving poverty, under the current distributional structure.

Even with the growth rates targeted in AsgiSA, neither the poverty gap nor the poverty headcount ratio can be halved with the current distribution of income or expenditure. Growth at the AsgiSA targeted rates would make significant inroads into poverty—cutting the poverty headcount ratio by about a third and the poverty gap by around 45 per cent. Even with the food poverty line, growth at the rates targeted in AsgiSA would result in halving the poverty gap but not the poverty headcount ratio. If actual growth between now and 2014 is closer to the rates forecast by Treasury and by the banks, the proportion of people living under either poverty line is cut by far less than half.

It can be safely concluded that it is extremely unlikely that poverty can be halved through growth alone. This means that poverty will not be halved by 2014 in the absence of some form of pro-poor distributional change. Furthermore, these results show the effects of

alternative growth rates on poverty if distribution is unchanged; were distribution to worsen then of course even fewer people would be lifted out of poverty at any of these growth rates.

TIP curves are utilised to show both the poverty gap and poverty headcount ratio under the current distributions of income and expenditure, and subsequently to explore the relationship between distribution, poverty, and growth and specifically to assess what combinations of growth and distributional change would allow for the halving of the poverty gap and poverty headcount ratio. Derived from Jenkins and Lambert (1997), 'TIP' refers to the 'Three I's of Poverty': the incidence, intensity, and inequality of poverty. TIP curves plot the cumulative sum of the poverty gaps per capita (y-axis) against the cumulative population share (x-axis).

Formally the TIP curve can be denoted (following Jenkins and Lambert) as *TIP(g; p)* where *p* is the cumulative population share with $0 \leq p \leq 1$ and *p* on the x-axis is plotted against $\sum_{i=1}^{k} \frac{g_i}{n}$.

Thus $TIP(g; \frac{k}{n}) = \sum_{i=1}^{k} \frac{g_i}{n}$ for $k \leq n$ (with intermediate points derived through linear interpolation).

The slope of the TIP curve at any given percentile equals the poverty gap for that percentile. For the subset of the population falling below the poverty line, the TIP curve is an increasing concave function of *p*, while for people above the poverty line the curve is horizontal (since their poverty gaps are zero). Insofar as the curve flattens as it approaches the poverty line, this shows the decline in the poverty gap as expenditure or income increase towards the threshold.
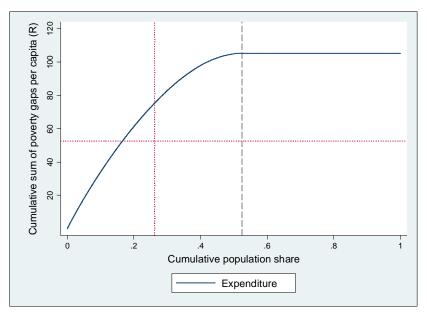

The extent of poverty incidence, in terms of the poverty headcount ratio, is shown by the value of *p* at the point where the curve becomes horizontal. This is shown by the length of the non-horizontal part of the TIP curve.

The intensity of poverty is shown by the overall height of the TIP curve, since the height of the curve (at *p=1*) is the aggregate poverty gap averaged over the entire population. The average poverty gap amongst the population falling below the poverty line is given by the slope of a ray from the origin to (*h, TIP(g; h)*).

The degree of inequality amongst the poor is shown by the degree of concavity of the non-horizontal section of the TIP curve. If all of the poor had equal incomes then the non-horizontal section of the curve would be a diagonal straight line (with a gradient equalling the difference between the poverty line and the average income of the poor).
Figure 1 shows the TIP curve for current expenditure (on a household per capita basis, per month). The curve plots over 47 million individual points, the cumulative poverty gaps of every South African (weighted from the original survey data). It can be seen that about half of the population currently falls under the poverty line of R450 per capita per month. Halving the poverty headcount ratio would mean cutting it to about a quarter. This target for the headcount ratio is shown by the dotted vertical line at around 0.26. The mean poverty gap per capita over the whole population is about R105 per capita per month. Halving the poverty gap would mean bringing it down to about R53 per capita, and this target is shown by the horizontal dashed line. Meeting the targets of halving both the poverty gap and the poverty headcount ratio would mean bringing the point of the TIP curve at which it becomes flat below the horizontal dotted line as well as to the left of the vertical dotted line.
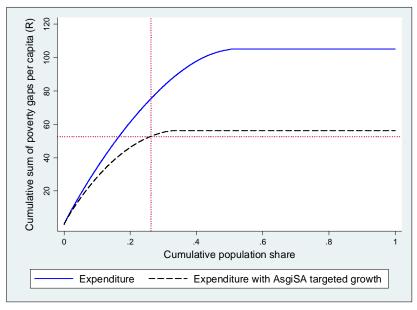

Figure 1: TIP curve of expenditure

Note: Poverty line set at R450 per capita per month, as discussed in the text (Figures 1-4).
Source: Author's calculations using Income and Expenditure Survey 2005/6 data

In Figure 2 below the original TIP curve for expenditure is compared with that which would result if the growth rates targeted in AsgiSA were to materialise through to 2014, given the current distribution of expenditure. The pattern of expenditure that would derive from that is shown as a dashed curve. Using the Treasury or banks' forecasts would yield TIP curves in between these two curves.

Figure 2: TIP curve of expenditure and expenditure with AsgiSA targeted growth rate

Source: Author's calculations using Income and Expenditure Survey 2005/6 data

With the growth rates as hoped for in AsgiSA, the poverty gap is reduced drastically and the poverty headcount ratio also falls significantly. Despite this, it can be seen that neither the poverty gap nor the poverty headcount ratio is actually halved. Even in the extremely

improbable event of the AsgiSA-targeted growth rates materialising, this would be insufficient to halve poverty without some pro-poor distributional change (in the sense of distributional change that disproportionately raises the income and expenditure of the poor).

With the current distribution, it would take many years of growth to halve poverty (in particular, the poverty headcount ratio). Were GDP to grow at an annual rate of 4 per cent per annum, both measures of poverty would not be halved until the year 2022. With GDP growth of 3 per cent per annum, only in the year 2027 would poverty be halved. This dramatically illustrates that relying on growth to bring down poverty would effectively mean that poverty would not be halved for a long time to come.

4   Poverty outcomes under alternative growth/distributional scenarios

a)   Distributional changes

Having established the improbability of growth alone leading to the halving of poverty by 2014, given the current distribution of income and expenditure, we thus examine what growth-distribution scenarios could produce the result of halving poverty by 2014.
There is an almost infinite variety of hypothetical distributional changes that could result in a halving of poverty. Distributional changes across the entire population are considered in the scenarios that follow, as explained below. Of course this is not how distributional change occurs in practice, and it would be very difficult to design policies to affect these outcomes with any degree of precision (and redistributional changes would of course also incur significant administrative costs and other types of transaction costs).

The concern here is not so much a direct redistribution of income through social transfers, although this could certainly be a component of distributional change. The analysis is concerned more fundamentally with an overall shift in the growth path towards more 'pro-poor growth', in the sense of growth in which the incomes of the poor increase relatively more than do those of the non-poor. The distributional changes simulated here are intended to be indicative of the scale of 'redistribution' of incomes and expenditure that would result from a more pro-poor growth path. For instance, one in which returns to unskilled labour rose more rapidly than returns to skilled labour, and/or a relative expansion in employment opportunities. Such a shift would not result in the exact distributional changes simulated here; these projections are indicative in nature and are suggestive as to what combinations of growth and a more egalitarian distribution could result in a halving of poverty.

b)   Method for simulating distributional changes

The methodology used in simulating alternative distributional scenarios is set out below with reference to income for heuristic purposes, but these were undertaken with each of income and expenditure. The method is explained intuitively here, and mathematically in Appendix 1.

We begin by ranking the entire South African population from highest to lowest in terms of household per capita income. The distributional changes simulated here 'revolve' around a

specific point in the distribution. In the simplest case this is the median income earner. We have also used the person at the 66.6th percentile (i.e. where a third of people have higher incomes) and the 75th percentile. This 'anchor' point is the only person whose income is unaffected by the distributional change (Since weights are being used this is not necessarily an actual individual, but the principle is the same.) Everyone with a higher income than this person loses from the distributional change and everyone below that person gains. The extent to which someone loses or gains depends on how far they are from the unaffected person: the highest income earner loses most while the lowest gains most. The simulated distributional change is generally rank-preserving because of the relatively small increments spread continuously over a population of over 47 million, with a small number of marginal re-rankings.

In the simplest case in which distributional change revolves around the median income earner, the change is symmetrical around that point. The loss of the highest income earner is the exact gain of the lowest; the loss of the second highest income earner is the gain of the second lowest; and so on. In this case the distributional change is both mean-preserving and median-preserving.

In a slightly more complex variation, the point around which the distributional change revolves is not the median income-earner (i.e. the 50th percentile), but the person at for instance the 66.6th or 75th percentile. In these cases the distributional changes simulated are mean-preserving but not median-preserving, and the distributional change is not symmetrical around the person whose income remains constant. If for example the change in the distribution revolves around the 75th percentile, the gain of the bottom three income earners must be matched by the loss of the top income earner, the gain of the next three income earners must be matched by the loss of the second highest income earner, and so on.

One parameter of these transformations is the 'scale' of the distributional change, in terms of how much income is redistributed. The simplest way to think about this is to set by how much the income of the lowest earner should grow through the distributional change. Simulations have been run here in which the income or expenditure of the bottom income earner grows by amounts ranging from between R50 [US$7.40] and R300 [US$44.4] per month. While this would constitute a very significant increase in income for someone at the lowest end of the distribution, the negative effect at the top of the distribution is but a miniscule fraction of the income of the highest earners.

For example, in the case of a distributional change in which the income of the lowest income person rises by R50 and the distributional change revolves around the median, the income of the highest income person would decline by R50. The income of the second lowest income person would rise by just under R50 and that of the second highest income by fall by just under R50 and so on, with the amounts falling uniformly from both sides until reaching zero at the median. In the case of a distributional change of a maximum R50 but revolving around the 75th percentile, the income of the lowest income person rises by R50 while the income of the highest income person declines by R150, with the absolute amounts declining from both ends (but in larger increments for the top quarter of the distribution) until reaching zero at the 75th percentile.

An alternative way of modelling distributional changes would have been simply to apply different growth rates to different parts of the distribution spectrum—for instance, that the income or expenditure of the bottom decile grows at 7 per cent, that of the next decile at 6.5

per cent, and so on. However, such a method is much cruder than the one have employed in this study. The method used here avoids an outcome where the income or expenditure of the person at the top end of the bottom decile grows significantly more than that of the person just above them at the bottom of the next decile. In the method employed here, the growth rates vary not by income category (e.g. deciles) but by individual, resulting in a much more continuous distributional change across the distributional spectrum.

Note that the 'losers' from the distributional change, at the upper end of the distribution, do not actually suffer any net loss of income or expenditure in the scenarios set out below, as these simulated distributional changes are combined with various growth scenarios. The income or expenditure at the top still grows considerably in every scenario (and far more than other people in absolute terms), but slightly less than it would have in the absence of the equalising distributional change.

This analysis does not model the causal relationships between growth and distribution. It uses micro-data to simulate distributional changes and to combine these changes with various growth rates in order to quantify the effects on poverty.

c) Projected poverty outcomes under various growth/distributional scenarios

Growth rates averaging between 1 per cent and 7 per cent per annum through to 2014 are considered here. While the upper growth scenarios are not at all likely to materialise, they are included here for the purposes of comparing various growth/distribution combinations.

We thus simulate the effects on the poverty gap and headcount ratio of 84 different combinations of growth and distributional change, for each of income and expenditure. These scenarios combine seven alternative growth rates (1 per cent, 2 per cent, 3 per cent, 4 per cent, 5 per cent, 6 per cent, and 7 per cent annual average growth rates through to 2014) with four different 'intensities' of pro-poor distributional change (in which the income of the lowest income person rises by R50, R100, R200, or R300) and in which distributional change revolves around each of the median, the 66.6[th] percentile, and the 75th percentile. This allows for a consideration of the effects on poverty of combining growth with a change in distribution that benefits the poor.

Poverty outcomes under two such scenarios are shown in Figure 3 for illustrative purposes. The solid line shows the expenditure pattern that would result from 6 per cent GDP average growth per annum through to 2014, combined with a progressive distributional change in which the poorest South African is just R50 better off than they would otherwise have been. The dashed line shows a scenario in which growth is fairly low at 2 per cent per annum but there is a more intensive distributional change, with the lowest-expenditure person gaining an additional R200 per month (with decreasing amounts thereafter, as explained earlier). The poverty gap is halved in both of these scenarios (as can be seen by the fact that both curves lie below the horizontal dotted line). However, while the poverty headcount ratio is reduced in both cases, this is by less than half (both curves flatten out a bit to the right of the vertical dotted line). Neither of these particular growth/distribution combinations is quite enough to halve the proportion of people living below the poverty line.
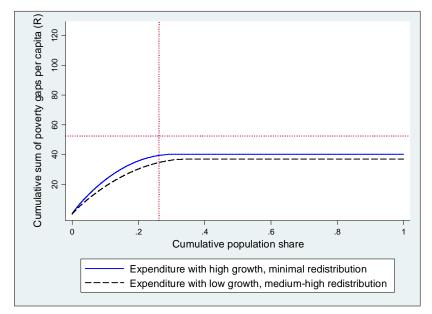

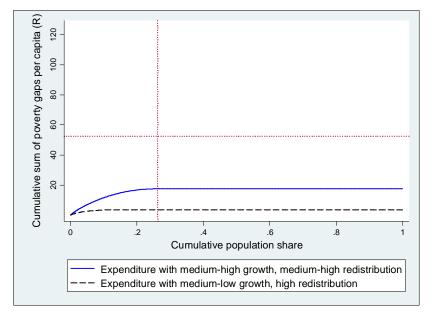

Figure 3: TIP curve of expenditure under alternative growth/distribution scenarios

Source: Author's calculations using Income and Expenditure Survey 2005/6 data

Figure 4: TIP curve of scenario halving poverty gap and headcount ratio

Source: Author's calculations using Income and Expenditure Survey 2005/6 data.

Figure 4 shows two growth/distributional scenarios in which both the poverty gap and the poverty headcount ratio are halved. In the scenario depicted with a solid line, GDP grows at 4 per cent per annum, while in terms of distribution the expenditure of the poorest person is R200 per month higher than would otherwise be the case. The dashed line shows a scenario of GDP growth of 3 per cent per annum with distributional change where the expenditure of the poorest person is raised by R300 per month. The TIP curves for both scenarios fall well below the horizontal dotted line, indicating that the poverty gap is actually cut by much more than half (in the second scenario the poverty gap is actually cut by almost 80 per cent). Both curves flatten out to the left of the vertical dotted line, showing that the poverty headcount

ratio is cut by at least half (in the second scenario it falls as far down as low as 12 per cent). In these growth/distribution scenarios the target of halving poverty is thus achieved on both counts.

Table 5 summarises whether the targets of halving the poverty headcount ratio and the poverty gap could be met under a range of growth/distribution scenarios. While these results are shown for expenditure, there is only very minor variation for income. The effects of GDP growth through to 2014 at averages of 1-7 per cent per annum are considered. These growth rates are shown here combined with four different pro-poor distributional scenarios. Following the method described earlier, in the most 'intensive' distributional change the maximum gain is R300 per month, which benefits the very poorest person, with the gains decreasing from there. In the least 'intensive' distribution scenario shown here, the lowest expenditure person gains by only R50 per month; intermediate scenarios of R100 and R200 are also shown. The results shown here are for distributional changes revolving around the 66.6th percentile. For each scenario Table 5 indicates whether or not the target of halving poverty is met. Since the halving of poverty is being considered in terms of halving both the poverty headcount ratio and the poverty gap, in each scenario an 'H' indicates that the poverty headcount ratio is (at least) halved while a 'G' indicates that the poverty gap is (at least) halved. The eleven scenarios in which both dimensions of poverty are halved are shaded in.

Table 5: Meeting of poverty targets under alternative growth/distribution scenarios

	Distribution				
	R300	R200	R100	R50	None
Growth					
7%	H, G	H, G	H, G	- ,G	- ,G
6%	H, G	H, G	- ,G	- ,G	- ,G
5%	H, G	H, G	- ,G	- ,G	-, -
4%	H, G	H ,G	- ,G	-, -	-, -
3%	H, G	- ,G	- ,G	-, -	-, -
2%	H, G	- ,G	-, -	-, -	-, -
1%	- ,G	- ,G	-, -	-, -	-, -

Notes: Growth refers to the average annualised growth rate between 2006 and 2014 under the various scenarios.

Distribution refers to the distribution scenarios as set out in the text. R300 means that the expenditure of the lowest-income person is R300 per month higher than it would otherwise have been (with amounts decreasing from there as income rises); similarly for R200, R100, and R50.

For each scenario (growth/distribution combination), H means that the poverty headcount ratio is at least halved and G indicates that the poverty gap is at least halved; – means that those measures are not halved.

Source: Author's calculations using Income and Expenditure Survey 2005/6 data.

Even under a (unrealistically optimistic) scenario of 7 per cent annual growth through to 2014, the poverty headcount ratio cannot be halved without some distributional change. Conversely, even with growth as low as 2 per cent per annum, both the poverty gap and poverty headcount ratio can be halved with distributional change in which the poorest person consumes an additional R300 per month.

d) Projected poverty outcomes under various growth/distributional scenarios

In the final part of the empirical analysis, the reduction in poverty in each of the 35 scenarios is decomposed into the relative contributions of growth and distributional change. This

analysis follows Datt and Ravallion (1992). While it is obvious that in the scenarios which combine high growth rates with limited pro-poor distributional change, growth will make a relatively higher contribution to poverty reduction than in a scenario combining low growth rates with significant pro-poor distributional change, but the decomposition analysis precisely quantifies the relative contributions of each.

Table 6: Decomposition of change in poverty headcount ratio under alternative growth/distribution scenarios

Growth		Distribution				
		R300	R200	R100	R50	None
7%	Δ in H	-49.6	-39.0	-29.4	-25.7	-22.7
	of which:					
	growth (%)	67.8	75.6	86.4	92.8	100.0
	distribution (%)	32.2	24.4	13.6	7.2	0.0
6%	Δ in H	-48.7	-35.5	-25.7	-22.3	-19.8
	of which:					
	growth (%)	64.4	73.8	85.9	92.7	100.0
	distribution (%)	35.6	26.2	14.1	7.3	0.0
5%	Δ in H	-47.0	-31.6	-21.9	-19.2	-16.7
	of which:					
	growth (%)	60.7	71.3	84.8	91.3	100.0
	distribution (%)	39.3	28.7	15.2	8.7	0.0
4%	Δ in H	-44.0	-26.9	-18.4	-15.4	-13.4
	of which:					
	growth (%)	56.3	67.7	82.5	90.5	100.0
	distribution (%)	43.7	32.3	17.5	9.5	0.0
3%	Δ in H	-40.3	-21.4	-14.3	-12.1	-10.3
	of which:					
	growth (%)	51.6	63.4	80.4	88.4	100.0
	distribution (%)	48.4	36.6	19.6	11.6	0.0
2%	Δ in H	-33.7	-16.6	-10.7	-8.9	-7.1
	of which:					
	growth (%)	45.6	56.2	74.9	83.9	100.0
	distribution (%)	54.4	43.8	25.1	16.1	0.0
1%	Δ in H	-22.6	-11.7	-6.6	-4.9	-3.1
	of which:					
	growth (%)	30.6	39.5	59.0	70.7	100.0
	distribution (%)	69.4	60.5	41.0	29.3	0.0

Notes: In each scenario (growth/distribution combination), 'Δ in H' refers to the change in the poverty headcount ratio, from its original level of 52.5. This change is decomposed into components of growth and distributional change. Thus, 'growth (per cent) shows the percentage contribution of growth to the reduction in the poverty headcount ratio, while 'distribution (per cent) shows the percentage contribution of distributional change to the reduction in the poverty headcount ratio; these components sum to 100 per cent in each scenario.

Source: Author's calculations using Income and Expenditure Survey 2005/6 data.

Table 6 summarises the results for the poverty headcount ratio and Table 7 for the poverty gap. Recall that the initial poverty headcount ratio was 52.46 per cent, such that halving the headcount ratio would require it to fall below 26.23 per cent. In each of the scenarios, Table 6 shows the change in the poverty headcount ratio that would result from that combination of

growth and distributional change. For example, in the first cell which combines a 7 per cent growth rate with distributional change in which the poorest person is R300 better off, the headcount ratio would fall by 49.6, with a resultant headcount ratio of under 3 per cent. When the reduction in the headcount ratio is decomposed into its growth and distributional components, it emerges that just over two thirds of the reduction is accounted for by growth and the remainder by distributional change. By contrast, in the scenario with R300 distributional change but with growth rates of only 1 per cent, almost 70 per cent of the reduction in the poverty headcount ratio is contributed by distributional change (and the absolute reduction in the headcount ratio is less than half that in the aforementioned scenario). It is noteworthy that in all but three of the scenarios shown here, it is growth rather than distributional change that contributes most to poverty reduction.

Table 7: Decomposition of change in aggregate poverty gap under alternative growth/distribution scenarios

Growth		Distribution				
		R300	R200	R100	R50	None
7%	Δ in G of which:	59.3	55.2	46.2	40.4	34.1
	growth (%)	52.5	62.0	75.6	85.7	100.0
	distribution (%)	47.5	38.0	24.4	14.3	0.0
6%	Δ in G of which:	59.1	53.8	43.4	37.0	30.2
	growth (%)	47.2	57.1	71.7	83.1	100.0
	distribution (%)	52.8	42.9	28.3	16.9	0.0
5%	Δ in G of which:	58.9	52.1	40.1	33.2	26.0
	growth (%)	41.5	51.7	67.2	79.9	100.0
	distribution (%)	58.5	48.3	32.8	20.1	0.0
4%	Δ in G of which:	58.5	49.9	36.5	29.1	21.4
	growth (%)	35.2	45.2	61.3	75.4	100.0
	distribution (%)	64.8	54.8	38.7	24.6	0.0
3%	Δ in G of which:	57.8	47.1	32.5	24.6	16.5
	growth (%)	28.2	37.6	53.5	69.1	100.0
	distribution (%)	71.8	62.4	46.5	30.9	0.0
2%	Δ in G of which:	56.8	43.8	28.0	19.8	11.4
	growth (%)	20.5	28.2	42.9	59.2	100.0
	distribution (%)	79.5	71.8	57.1	40.8	0.0
1%	Δ in G of which:	54.9	39.9	23.2	14.6	5.8
	growth (%)	11.3	16.1	26.9	41.5	100.0
	distribution (%)	88.7	83.9	73.1	58.5	0.0

Notes: In each scenario (growth/distribution combination), 'Δ in G' shows the change (in R billion) in the aggregate poverty gap, from its original level of R59.8 billion. This change is decomposed into components of growth and distributional change. Thus, 'growth (per cent) shows the percentage contribution of growth to the reduction in the poverty gap, while 'distribution (per cent) shows the percentage contribution of distributional change to the reduction in the poverty gap; these components sum to 100 per cent in each scenario.

Table 7 shows the decomposition results for the poverty gap. As discussed earlier, the initial aggregate poverty gap was R59.82 billion, so halving it would mean cutting it to below R29.81 billion. To take the example of the scenario combining a 3 per cent growth rate with distributional change in which the poorest person is R100 better off than would otherwise be the case, the aggregate poverty gap falls by R32.5 billion, such that it is cut by a bit more than half, with just over half of this reduction contributed by growth and just under half by distributional change.

The key difference when compared to the results for the poverty headcount ratio is that the distributional change component plays a more significant role here. Growth and distributional change play approximately balanced roles in the reduction of the poverty gap, for the scenarios investigated. The more significant relative contribution of distributional change in the reduction of the poverty gap, as compared to the reduction of the poverty headcount ratio, would relate to the fact that the changes in the consumption of those at the bottom that do not move out of poverty, do not enter into changes in the headcount ratio, as discussed earlier. However, improvement in the consumption of those at the bottom does significantly affect changes in the poverty gap. Since the types of distributional changes modelled here affect the consumption of those at the bottom the most, it follows that distributional change will affect the poverty gap relatively more than it would the poverty headcount ratio.

5 Discussion

Given South Africa's levels of income per capita and status as an upper-middle income country, the scale of poverty is associated more with distributional patterns than with the total amount of resources available. Poverty in South Africa would be far lower than it is, were distribution to be at anything approaching a typical level of inequality by international standards.

While decent rates of growth could make some inroads into poverty, given the scale of poverty growth alone will fall short.[10] Internationally, Bourguignon (2004) emphasises that distribution matters for poverty reduction, and that comparative international evidence indicates that over the medium run distributional changes can account for significant increases or decreases in poverty. Highlighting the country specificity of this relationship, he suggests that changing the distribution is likely to be more important than growth, for reducing poverty in middle-income and inegalitarian countries. South Africa is a classic instance of such countries. The simulations of the effects of various growth/distributional scenarios suggest that halving poverty by 2014 requires a 'pro-poor' shift in the growth trajectory (over and above the distributional policies currently in place), such that distribution becomes less unequal.

---

[10] In terms of the relationship between growth and poverty, Adams (2004) finds that economic growth reduces poverty in developing countries, but the rate of this reduction depends heavily on how growth is defined and measured. For African countries, Fosu (2008) finds that greater income equality would positively affect the impact of growth on poverty reduction, although there is a high degree of heterogeneity among countries. Fanta and Upadhyay (2009) find that, for a sample of 16 African countries, growth reduces poverty, with estimated elasticities between -0.5 and -1.1. For studies of the growth-inequality-poverty relationship in other parts of the world, see for example Wodon (2000), Enders and Hoover (2003) and Gibson (2000).

A broader issue involves the causal relationship between growth and distribution. There is a corpus of literature on the effects of inequality on growth, and another concerning the effects of growth on inequality. The impact of growth on distribution is a priori indeterminate, and would be contingent on country-specific factors such as relative factor endowments and rewards (e.g. to labour and capital, and to various skills categories). The relationship is also affected by the sectoral character of growth, in terms of relative productivity in different sectors and the distributional characteristics of the sectors in which growth is highest. Broader political economic and institutional issues also affect the way in which growth affects distribution, including factors such as the power of various groups, and the impact of growth on institutions and culture. Empirically, according to Bourguignon (2004) there is too much country specificity in the impact of growth on inequality to allow for any generalisation. Similarly, Ravallion (1995) finds that there are no systematic effects of growth on poverty.

The classical conception of the relationship between inequality and growth was expressed in Kuznets' inverted-U curve, according to which inequality initially rises with income per capita but falls at higher levels of income per capita. Especially in the earlier literature, this was interpreted as pointing to a trade-off between growth and equity, up to the turning point of the inverted-U. According to Bourguignon and Morrison (1998), the inverted-U hypothesis was borne out empirically in the 1970s but not since then. Zweimüller (2000) points to increases in inequality in several major OECD countries over the past three decades or so, but with significant variation between countries. According to Deininger and Squire (1998) there is very little support for a Kuznets curve when considering time-series data for most countries of the world.

In terms of the causal relationship from inequality to growth, it has been argued in the literature that inequality can be beneficial for growth, *inter alia* through the incentivisation of work effort and risk-taking; the promotion of innovation; higher savings rates being associated with higher inequality; and concentration of wealth allowing for the large initial investments required for some types of production. Recent empirical work supporting a positive relationship between inequality and growth includes Forbes (2000) who finds evidence that, in the short and medium term, an increase in a country's level of income inequality has a significant positive effect on subsequent growth.

Conversely, an extensive theoretical and empirical literature has emerged that points to a negative causal relationship from inequality to growth; see for instance Alesina and Rodrik (1994), Aghion et al (1999), Persson and Tabellini (1994), Clarke (1995), and Deininger and Squire (1998). Channels identified by various authors for such a relationship include imperfections in capital, credit and insurance markets associated with inequality that negatively affect investment and growth; that high inequality can encourage policies that are detrimental to growth; negative effects of inequality on work effort and productivity; conflict and instability and weak social capital associated with high inequality; and inefficient allocation of education resources with a deleterious effect on human capital formation.

Ferreira (1999) characterises the recent state of the inequality-growth debate as being that income inequality might not directly affect growth but that it proxies for wealth inequality, and that wealth inequality does have a significant negative effect on growth. While the debate concerning the nature of the influence of inequality on growth remains open, the preponderance of arguments and evidence particularly in the past fifteen years or so points to negative effects of inequality (especially very high inequality) on growth.

Given that South Africa is one of the most unequal countries in the world, this could suggest that reducing inequality could be beneficial not only for reducing poverty but also for increasing growth. To the extent that a reduction in inequality could contribute to raising the growth rate, this could suggest that pro-poor distributional changes such as those simulated here might support higher growth, thus making the scenarios which combine a reduction in inequality with higher growth easier to achieve than would otherwise be the case.

The actual effects of a specific reduction of inequality on growth would of course be contingent on the nature of that reduction and how it came about. The types of policies that could be considered for the reduction of inequality in South Africa might include land reform and other forms of asset redistribution; a more progressive taxation system; increased expenditure directed at improving the incomes and capabilities of the poor; a more equitable education system; measures to reduce unemployment and in particular to increase employment opportunities for the unskilled and semi-skilled; labour market interventions to narrow the wage gap; and measures to influence the sectoral structure of the economy in favour of sectors from which low-income earners derive a greater share of income. A consideration of the specifics of policy options for reducing inequality, and the implications of such options for growth, fall beyond the scope of this study. More pertinently, insofar as reducing the extremely high level of inequality in South Africa would support a higher rate of growth, then such measures could be considered not only for the purposes of reducing inequality and poverty but also for improving growth performance. This is also germane to the feasibility of scenarios combining reduced inequality with higher growth rates.

Dramatic improvements in distribution rarely come about without active measures targeted specifically at lessening inequality. Moderate decreases in inequality may well materialise as a by-product of other dynamics. However, the magnitude of the reduction in inequality that would be required to bring South Africa anywhere in line with international norms is realistically not going to happen without policies dedicated to that end. The distributional changes analysed here would not even bring South Africa down to typical levels of inequality for a middle-income country, but to the range of highly unequal countries such as Brazil.

A stylised fact of distributional changes internationally, at least in recent decades, is what might be termed a 'downward stickiness' of inequality (see Palma, 2007). Increases in inequality are much less reversible than are decreases. For instance, in countries where a government comes into power and institutes conservative economic policies that worsen income distribution, is followed by the election of a government that switched to more 'progressive' policies, the distribution of income typically hardly comes down, and certainly not down to the initial levels. Even where the intention is genuinely to improve income distribution, this often turns out to be far more difficult than anticipated. This is not surprising, as the wealthy are generally far better able to protect their income than are the poor, as well as being better placed to reverse any 'unfavourable' changes in distribution that do occur. This asymmetry in distributional changes underlines the point that a significant improvement in income distribution is highly unlikely to materialise without strong policy interventions geared towards that goal. Improving income distribution is possible, but it takes effort.

With the poverty line as defined here, the aggregate poverty gap is only about 3 per cent of GDP. This suggests that poverty in South Africa should not be viewed as an insurmountable problem. In fact, given that half of the population falls below that line, 3 per cent of GDP is a

comparatively small amount, and is smaller than what might have been expected before analysing the data. Of course the actual cost of eliminating poverty would significantly exceed this amount if considered in terms of direct transfers (given issues of targeting and administration).

Nonetheless, considering the huge scale of poverty in terms of its incidence, in conjunction with the rather small scale when considered in terms of GDP, does suggest the feasibility of dramatic reductions in poverty. If this proves intractable through a shift in the growth path, direct transfers could prove effective (as they have been in the case of Brazil). The extreme levels of inequality in South Africa would seem to suggest that there is considerable scope for pro-poor distributional change.

6   Conclusion

First, the target of halving poverty by 2014 does appear to be feasible, under growth rates that are a bit lower than in recent years and with quite mild distributional change. For instance, poverty could be halved with growth rates of 2 per cent combined with distributional change in which the poorest person can consume a maximum of R300 more per month, or alternatively growth of 4 per cent per annum combined with distributional change where the poorest person consumes a maximum of R200 more per month. It might be suggested therefore that this target should not be given up on or treated as some distant goal or rhetorical aspiration. This is reinforced by the fact that the entire poverty gap in South Africa (using the poverty line specified here) is just 3 per cent of GDP.

Second, however, it is highly improbable that the target of halving poverty will be attained in the absence of a pro-poor shift in the growth trajectory. Growth alone will not enable the halving of poverty. Furthermore, it is unlikely that the growth path would endogenously evolve in a sufficiently pro-poor way, without active policy interventions designed to achieve this shift.

Third, given that government is still finalising the level of the national poverty line, the possible temptation for policymakers to set this too low should be avoided. It currently appears that, notwithstanding the background research by Statistics SA into the minimum amount which could be used for a poverty line, government is considering setting it even lower than this level. This might be motivated at least in part by the realisation of just how many people would fall under such a line, and perhaps a concern that it would be difficult to halve that number of people within a reasonable timeframe. One insight that emerges from this analysis is that even middling growth with no distributional change goes a long way towards halving of poverty by 2014, and with what might be considered fairly mild pro-poor distributional change the halving of poverty appears to be feasible. While a poverty line in the region of R450 [US$67] per capita per month (as used in this analysis) means that about half of all South Africans would currently be classified as poor, this should not necessarily motivate the choice of a lower poverty line given the feasibility of dramatically cutting poverty over the next few years.

Distributional changes would of course not in practice materialise in the manner modelled here, but these simulations are indicative of the scale of distributional changes needed to halve poverty. The most important dynamic underlying actual distributional changes are likely to be through the labour market, in terms of both employment creation (or losses) and

the distribution of earnings amongst the employed. Social spending certainly has a role to play in ameliorating inequality and poverty, particularly in the short to medium term. However, South Africa's inequality is unlikely to be brought down to 'decent' levels—at least to 'normal' standards of inequality internationally—through social spending, but rather through increased demand for low and semi-skilled labour and through a closing of wage gaps.

This underlines the imperative of pro-poor distributional change if poverty is to be halved by 2014. Scenarios combining various growth scenarios with a range of simulations of pro-poor distributional change point to the feasibility of halving poverty by 2014. Inequality in South Africa is extremely high by international standards. If policymakers in South Africa are serious about halving poverty, active interventions would be needed to avoid any worsening of inequality and actually to reduce inequality – specifically, the shares of income and expenditure going to the bottom half of the population. In this vein it might be suggested that the reduction of inequality be placed as a more central and explicit goal of government policy than is currently the case, both for its own sake and in order to significantly reduce poverty. Whether the reduction of inequality is a desirable goal in its own right is obviously a political issue. An associated consideration, if indeed the reduction of inequality is a public policy objective, is how strongly and in what ways this is to be pursued insofar as there are tensions between this and other policy goals.

Finally, the method developed here for simulating distributional changes could be applied to investigating the impact of various combinations of growth and pro-poor distributional change in other countries; this could be particularly valuable in the light of the Millennium Declaration goal of halving extreme poverty internationally by 2014.

Appendix 1: Method used for simulating distributional changes

To set out the method described in section 4 more formally, let x_i denote the income or expenditure of person i where the population is ranked from lowest to highest in terms of variable x, for $i = 1,2,...,n$. That is, x_1 is the lowest income or expenditure and x_n the highest. Note that this ranking will differ for income and for expenditure. In this analysis, $n = 47\ 391\ 192$.

Select ρ, the point around which the distributional change will revolve. For symmetrical distributional change around the median, $\rho = 0.5n$; for distributional change around the person at for example the 75th percentile, $\rho = 0.75n$.

Let θ_i be the value of the distributional change affecting person i such that:

$\theta_i > 0$ for $i < \rho$;

$\theta_i < 0$ for $i > \rho$; and

$\theta_i = 0$ for $i = \rho$.

Select ω, the value of the gain to the person with the lowest income or expenditure [$i=1$].

The range of values to be redistributed will be:
$\omega \le \theta_i \le |\phi|$ where ϕ is the maximum loss to the person with the highest income or expenditure [$i=n$] and $\omega > 0$ and $\phi < 0$.

For the special case of distributional change revolving around the median ($\rho = 0.5n$),
$\omega = -\phi$;
while for distributional change around points higher than the median (e.g. $\rho = 0.75n$),
$\omega < |\phi|$.

Then for $i < \rho$, the distributional gain will be:

$$\theta_i = \omega - \frac{\omega(i-1)}{\rho-1} = \frac{\omega(\rho-i)}{\rho-1}.$$

It can be seen that for the poorest person, the distributional gain will be the full value of the maximum distributional change, ω, while for the person just below the unaffected person (e.g. immediately below the median person in the simplest case) the distributional gain will be positive but close to zero.

For $i > \rho$, the distributional loss will be:

$$\theta_i = (\rho-i)\frac{\sum_{i=1}^{\rho-1}\theta_i}{\sum_{i=\rho+1}^{n}(i-\rho)}.$$

This is a general expression which mathematically balances the aggregate loss to upper-income earners with the aggregate gain to lower-income earners who gain from distributional change, no matter around which point the distributional change revolves.

Note that in this exposition we have selected the maximum gain to the person with the lowest income or expenditure [$i=1$], ω, then calculated the gain to the other people in subset $i < \rho$; this allowed for the derivation of the loss to the people in subset $i < \rho$.

The method could equally have begun by selecting the loss to the person with the highest income or expenditure [$i=n$], ϕ, and calculating $\theta_i \; \forall \; i > \rho$ and thence deriving $\theta_i \; \forall \; i < \rho$; the results would be identical.

The post-distributional-change income of person i will thus be:
$$\tilde{x}_i = x_i + \theta_i$$

Such that
$$\tilde{x}_i > x_i \; \forall \; i < \rho; \quad \tilde{x}_i = x_i \; for \; i = \rho; \quad and \; \tilde{x}_i < x_i \; \forall \; i > \rho.$$
